ABSTRACT

High-dimensional neural activity in the brain is known to encode low-dimensional, time-evolving, behaviour-related variables. A fundamental goal of neural data analysis consists of identifying such variables and their mapping to neural activity. The canonical approach is to assume the latent variables *are* behaviour and visualize the subsequent tuning curves. However, significant mismatches between behaviour and the encoded variables may still exist — the agent may be thinking of another location, or be uncertain of its own — distorting the tuning curves and decreasing their interpretability. To address this issue a variety of methods have been proposed to learn this latent variable in an unsupervised manner; these techniques are typically expensive to train, come with many hyperparameters or scale poorly to large datasets complicating their adoption in practice. To solve these issues we propose SIMPL (Scalable Iterative Maximization of Population-coded Latents), an EM-style algorithm which iteratively optimizes latent variables and tuning curves. SIMPL is fast, scalable and exploits behaviour as an initial condition to further improve convergence and identifiability. We show SIMPL accurately recovers latent variables in biologically-inspired spatial and non-spatial tasks. When applied to a large rodent hippocampal dataset SIMPL efficiently finds a modified latent space with smaller, more numerous, and more uniformly-sized place fields than those based on behaviour, suggesting the brain may encode space with greater resolution than previously thought.

1 Introduction

Large neural populations in the brain are known to encode low-dimensional, time-evolving latent variables which are, oftentimes, closely related to behaviour (Afshar et al., 2011; Harvey et al., 2012; Mante et al., 2013; Carnevale et al., 2015; Kobak et al., 2016). Coupled with a recent data-revolution driven by the advent of large-scale neural recording techniques (Jun et al., 2017; Wilt et al., 2009), focus in recent years has shifted from single-cell to population-level analyses where the goal is to extract these variables using a variety of statistical (Yu et al., 2008a; Cunningham & Yu, 2014; Kobak et al., 2016; Zhao & Park, 2017; Williams et al., 2020) and computational (Van der Maaten & Hinton, 2008; Pandarinath et al., 2018; Mackevicius et al., 2019) methods, ultimately providing deeper insight into the computations embodied by neural circuits.

This paradigm shift is particularly pertinent in the context of the mammalian spatial memory system where Nobel-prize winning discoveries have identified cells whose neural activity depends on spatially-relevant behavioural variables such as position (O’Keefe & Dostrovsky, 1971; O’Keefe, 1978; Hafting et al., 2005; Doeller et al., 2010; Moser et al., 2015), heading direction (Taube et al., 1990), speed (McNaughton et al., 1983) and distance to environmental boundaries (Lever et al., 2009)/objects (Høydal et al., 2019) in a highly structured manner. These discoveries include place cells (O’Keefe & Dostrovsky, 1971) and grid cells (Hafting et al., 2005) which are widely held to constitute the brain’s

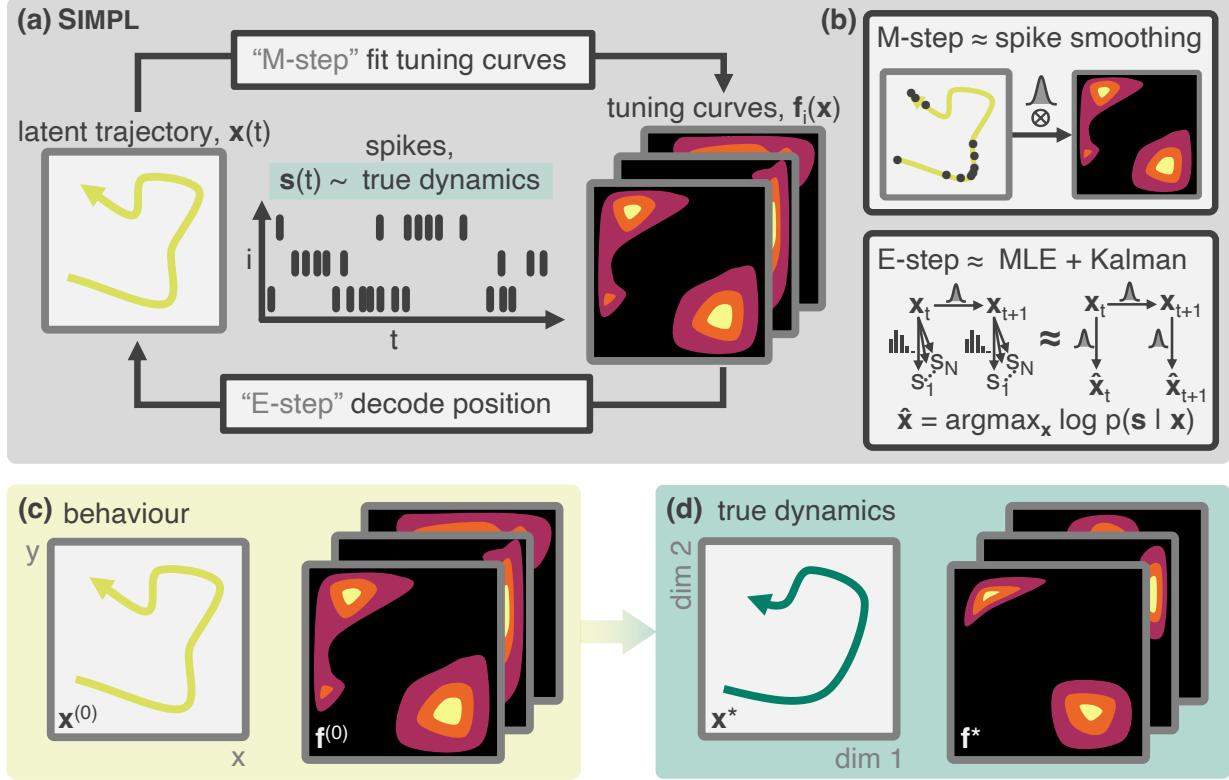

Figure 1: Schematic of the SIMPL algorithm. **(a)** A latent variable model for spiking data ($f_i(x)$, $x(t)$) is optimized by iterating a two-step procedure closely related to the expectation-maximization (EM, Dempster et al. 1977) algorithm: First, tuning curves are fitted to an initial estimate of the latent variable (the ‘M-step’), which are then used to redecode the latent variable (the ‘E-step’). **(b)** SIMPL fits tuning curves using kernel density estimation (KDE) with a Gaussian kernel (top) and decodes the latent variables by Kalman-smoothing maximum likelihood estimates. Measured behaviour **(c)** is used to initialize the algorithm as it is often closely related to the true generative latent variable of interest **(d)**.

“cognitive map” (Tolman, 1948; O’Keefe, 1978). Characterizing neural activity in terms of behaviour has been, and remains, a cornerstone practice in the field; however, the core assumption supporting it — that the latent variable encoded by neural activity *is and only is* the behavioural variable — is increasingly being called into question (Sanders et al., 2015; Whittington et al., 2020; George et al., 2024b).

The brain is not a passive observer of the world. Active internal processing like planning a future route (Spiers & Maguire, 2006) or recalling past positions (Squire et al., 2010) as well as observed phenomena such as replay (Carr et al., 2011), theta sweeps (Maurer et al., 2006), and predictive coding (Muller & Kubie, 1989; Mehta et al., 1997; Stachenfeld et al., 2017) will cause encoded variables to deviate from behaviour. Additionally, the brain is not a perfect observer; irreducible uncertainty due to limited, noisy or ambiguous sensory data can lead to similar encoding discrepancies. Experimental inaccuracies, like measuring the wrong behaviour or measuring behaviour poorly, can contribute further. These hypotheses are supported by decoding analyses which show that “behaviour” decoded from behaviourally-fitted tuning curves rarely achieves perfect performance (Glaser et al., 2020; Wilson & McNaughton, 1993) as well as the observation that neurons show high variability under identical behavioural conditions (Fenton & Muller, 1998; Low et al., 2018).

All combined, these facts hint at a much richer and more complex internal neural code. When this complexity is not accounted for (as is typically the case), neural data may be misinterpreted and tuning curves will be blurred or distorted relative to their true form, weakening the validity of the conclusions drawn from them. As an explicit example, consider an animal situated at position X ‘imagining’ or ‘anticipating’ another position, Y, for which a cell is tuned (e.g. the cell has a place field at Y). This might trigger the cell to fire leading a researcher, who only examines the animal’s externally measurable behavioural-position, to mistakenly conclude that the cell has a place field at location X. Nonetheless, the observation that behaviour is still a close-but-imperfect proxy for the true latent variable motivates the search for techniques to *refine* behaviourally fitted tuning curves as opposed to starting from scratch. Current methods either fail to exploit behaviour (Yu et al., 2008a; Wu et al., 2017), don’t scale to large neural datasets (Wu et al., 2017), are

computationally expensive to train (Smith & Brown, 2003; Pandarinath et al., 2018) or are limited in the expressiveness of their tuning curve models (Macke et al., 2011; Gao et al., 2016; Archer et al., 2014).

Contributions Here we introduce SIMPL (Scalable Iterative Maximization of Population-coded Latents), a straightforward yet effective enhancement to the current paradigm. Our approach fits tuning curves to observed behaviour and iteratively refines these through a two-step process: first we *decode* the latent variable from the previously estimated tuning curves; then, we *refit* the curves based on these decoded latents. SIMPL imposes minimal constraints on the structure of the tuning curves, scales well to large neural datasets and does not rely on neural network function approximators which can be hard to interpret and expensive to train. We theoretically analyse SIMPL and establish formal connections to expectation-maximisation (EM, Dempster et al. 1977) for a simple but flexible class of generative models. By exploiting behaviour as an initialization, SIMPL converges fast and alleviates well known issues to do with local minima and identifiability (Hyvärinen & Pajunen, 1999; Locatello et al., 2019). This allows it to reliably return refined tuning curves and latent variables which remain close to, but improve upon, their behavioural analogues readily admitting direct comparison.

We first validate and analyse the properties of SIMPL on synthetic datasets that closely match those analysed by experimentalists: a discrete 2AFC decision-making task and a continuous grid cells dataset. Finally, we apply SIMPL to rodent electrophysiological hippocampal data (Tanni et al., 2022) and show it modifies the latent space in an incremental but significant way. The optimized tuning curves explain the data better than their behavioural counterparts and contain sharper, more numerous place fields which allow for a reinterpretation of previous experimental results, motivating the use of SIMPL in future studies. SIMPL has only two hyperparameters and can be run on quickly on large neural datasets $\mathcal{O}(200 \text{ neurons}, 10^6 \text{ spikes}, 1 \text{ hour}) \sim \mathcal{O}(1 \text{ CPU-min})$ without requiring a GPU. It outperforms a popular modern alternative technique based on neural networks (Schneider et al., 2023) and is over $30\times$ faster. This make it a practical alternative to existing tools particularly of interest to navigational communities where data is abundant and behavioural variables are close to the true latent. We provide an open-source JAX-optimised (Bradbury et al., 2018) implementation of our code¹.

2 Method

Here we provide a high-level description of the SIMPL algorithm. Comprehensive details, as well as a theoretical analysis linking SIMPL formally to expectation-maximization of a class of generative models, is provided in the Appendix.

Algorithm 1 SIMPL: An algorithm for optimizing tuning curves and latents from behaviour

```

1:  $\mathbf{s} \in \mathbb{N}^{N \times T}$                                      ▷ Spike count matrix
2:  $\mathbf{x}^{(0)} \in \mathbb{R}^{D \times T}$                          ▷ Initial latent estimate e.g. measured position of animal
3: procedure SIMPL( $\mathbf{s}, \mathbf{x}^{(0)}$ )
4:   for  $e \leftarrow 0$  to  $E$  do                                ▷ Loop for  $E$  iterations
5:      $\mathbf{f}^{(e)} \leftarrow \text{FitTuningCurves}(\mathbf{x}^{(e)}, \mathbf{s})$           ▷ The “M-step”
6:      $\mathbf{x}^{(e+1)} \leftarrow \text{DecodeLatent}(\mathbf{f}^{(e)}, \mathbf{s})$           ▷ The “E-step”
7:   end for
8:   return  $\mathbf{x}^{(E+1)}, \mathbf{f}^{(E)}$                                ▷ The optimised latent and tuning curves
9: end procedure

```

2.1 The model

SIMPL models *spike trains* of the form $\mathbf{s} := (s_{ti})_{t=1,\dots,T}^{i=1,\dots,N}$, where s_{ti} represents the number of spikes emitted by neuron i between time $(t - 1) \cdot \Delta t$ and $t \cdot \Delta t$, for some time discretization interval Δt . We denote $\mathbf{s}_t := (s_{t1}, \dots, s_{tN})$ the vector of spike counts emitted by all neurons in the t -th time bin. SIMPL posits that such spike trains \mathbf{s} are modulated by a *latent, continuously-valued, low-dimensional, time-evolving* variable $\mathbf{x} := (\mathbf{x}_t)_{t=1,\dots,T} \in \mathbb{R}^D$ through the following random process:

$$\begin{aligned} s_{ti} \mid \mathbf{x}_t &\sim \text{Poisson}(f_i(\mathbf{x}_t)) \\ \mathbf{x}_{t+1} \mid \mathbf{x}_t &\sim \mathcal{N}(\mathbf{x}_t, \sigma_v^2 \mathbf{I}), \end{aligned}$$

where $\sigma_v := v \cdot \Delta t$ and $\mathbf{x}_0 \sim \mathcal{N}(0, \sigma_0^2 \mathbf{I})$. Here, v is some constant expected velocity hyperparameter. The resulting prior distribution $p(\mathbf{x}) = p(\mathbf{x}_0) \prod_{t=1}^T p(\mathbf{x}_t | \mathbf{x}_{t-1})$ enforces a tunable (through v) amount of temporal smoothness in

¹Code and a demo can be found at: <https://github.com/TomGeorge1234/SIMPL>

the trajectories. At each time step the latent variable \mathbf{x}_t determines the instantaneous firing rate of each neuron via its intensity function f_i (hereon called its *tuning curve*, collectively denoted \mathbf{f}), which is unknown a priori, and which SIMPL will estimate. Moreover, we make the common assumption that all neurons are *conditionally independent* given \mathbf{x}_t , i.e. $p(\mathbf{s}_t|\mathbf{x}_t) = \prod_{i=1}^N p(s_{ti}|\mathbf{x}_t)$. Finally, we assume the latent variable \mathbf{x} evolves only according to its previous state (it is Markovian), a common assumption in the neuroscience literature (see, e.g. George et al. 2021). This model has been previously studied in the literature (Smith & Brown, 2003; Macke et al., 2011), albeit using highly restrictive intensity function models, something which SIMPL avoids as discussed below.

2.2 The SIMPL algorithm

Outline We now seek an estimate of the true, unknown latent trajectory \mathbf{x}^* and tuning curves \mathbf{f}^* that led to some observed spike train, \mathbf{s} . SIMPL does so by iterating a two-step procedure closely related to the expectation-maximisation (EM) algorithm: first, tuning curves are fitted to an initial estimate of the latent variable (the “M-step”), which are then used to decode the latent variable (the “E-step”). This procedure is then repeated using the new latent trajectory, and so on until convergence.

The M-step In the M-step (or “fitting” step) of the e -th iteration SIMPL fits intensity functions to the current latent trajectory estimate $\mathbf{x}^{(e)}$ using kernel density estimation (KDE):

$$f_i^{(e)}(\mathbf{x}) := \frac{\sum_{t=1}^T s_{it} k(\mathbf{x}, \mathbf{x}_t^{(e)})}{\sum_{t=1}^T k(\mathbf{x}, \mathbf{x}_t^{(e)})} \approx \frac{\# \text{ spikes at } \mathbf{x}}{\# \text{ visits to } \mathbf{x}} \quad (1)$$

The use of a smooth kernel allows extrapolation of the intuitive estimate on the right of Equation 1 to locations not present in the trajectory $\mathbf{x}^{(e)}$. In practice, we use a Gaussian kernel with bandwidth σ .

The E-step In the E-step (or “decoding” step), SIMPL produces a new estimate $\mathbf{x}^{(e+1)}$ of the latent trajectory by smoothing — using the prior $p(\mathbf{x})$ — across time the (non-smooth) *maximum likelihood estimate* (MLE) $\hat{\mathbf{x}}$ of \mathbf{x} , given \mathbf{s} and $\mathbf{f}^{(e)}$. To do so, SIMPL computes a linear-Gaussian approximation of the conditional distribution $p(\hat{\mathbf{x}}_t|\mathbf{x}_t) \approx \mathcal{N}(\mathbf{x}_t; \Sigma_t)$. With this approximation, the variables $(\mathbf{x}, \hat{\mathbf{x}})$ form a Linear Gaussian State Space Model, fully characterized by $\sigma_v^2 I$ (the transition noise covariance) and Σ_t (the observation noise covariance). This allows SIMPL to employ *Kalman Smoothing*, an efficient inference procedure for such models, to approximate $\mathbb{E}_{p(\mathbf{x}|\hat{\mathbf{x}})}[\mathbf{x}]$.

Crucially, the linear-Gaussian approximation is *not* made on the spiking emissions $p(\mathbf{s}|\mathbf{x})$, which is non-Gaussian by design, but on $p(\hat{\mathbf{x}}|\mathbf{x})$, a quantity which is provably asymptotically Gaussian in the many-neurons regime (full theoretical argument and an explicit formula for Σ_t in B.1). At a high level, SIMPL’s E-step can thus be summarized as (see Fig. 1b, lower panel, for a graphical summary):

$$\begin{aligned} \hat{\mathbf{x}}^{(e+1)} &:= \arg \max_{\mathbf{x}} \log p(\mathbf{s}|\mathbf{x}, \mathbf{f}^{(e)}) \\ \mathbf{x}^{(e+1)} &:= \mathbb{E}_{p(\mathbf{x}|\hat{\mathbf{x}}_t^{(e+1)})} [\mathbf{x}] \approx \text{KalmanSmooth}(\hat{\mathbf{x}}^{(e+1)}; \sigma_v^2 \mathbf{I}, \Sigma_t) \end{aligned} \quad (2)$$

Behavioural initialization Spike trains often come alongside behavioural recordings which are thought to be closely related to the latent variable \mathbf{x} . SIMPL leverages this by setting $\mathbf{x}^{(0)}$, the initial decoded latent trajectory, to measured behaviour. We posit that such a *behavioural initialization* will place the first iterate of SIMPL in the vicinity of the true trajectory and tuning curves. This, in turn, facilitates the search for a good model which favours the true latent and tuning curves $(\mathbf{x}^*, \mathbf{f}^*)$ over alternative pairs $(\phi(\mathbf{x}^*), \mathbf{f}^* \circ \phi^{-1})$ whose latent space is *warped* by some invertible map ϕ , and which would explain the data equally well (i.e. solution pairs which are *isomorphic* to the ground truth). Through ablation studies, we confirm the beneficial effects of this behavioral initialization in the experiments section (see Fig. 3 and 4).

All in all, SIMPL is interpretable and closely matches common practice in neuroscience; moreover, it can be formally related to a generalized version of the EM-algorithm, for which theoretical guarantees may be obtained under suitable assumptions. We describe in detail the theoretical arguments justifying the validity of SIMPL as well as its connection to EM in the appendix.

3 Related work

Probabilistic inference in spike trains modulated by latent variables has been a major topic in neural data analysis for decades — see, e.g. Yu et al. (2005, 2006, 2008b,a); Macke et al. (2011); Mangion et al. (2011); Park et al. (2015); Gao et al. (2016); Duncker et al. (2019); Zhou & Wei (2020); Schneider et al. (2023). Closest to SIMPL are the works of

Smith & Brown (2003); Macke et al. (2011), which both perform approximate EM in a hidden markov model with Poisson emissions and a Gaussian random walk prior on \mathbf{x} . Both methods use a simplistic parametric linear-exponential model of intensity functions; such parametric models are not flexible enough to capture neurons with complex tuning properties such as place cells and grid cells. The (approximate) E-step of Macke et al. (2011) employs a global Laplace approximation, leveraging the concavity of the log-posterior of such models to compute the maximum a posteriori (MAP) of the entire trajectory; however, this concavity is a consequence of the intensity function model, and does not hold in our more complex case. On the other hand, the approximate E-step of Smith & Brown (2003) uses a *local* Laplace approximation to obtain the MAP. However, their algorithm requires running optimization algorithms sequentially, which can be computationally expensive. In contrast, the MLE optimization problems computed in SIMPL’s E-step can be solved in parallel across time points, making SIMPL more scalable.

Markovian models assume that the future trajectory of an agent is only influenced by its current state, not its past ones. This assumption may not accurately capture certain brain patterns with long range time dependencies. To address such issues, a series of methods, pioneered by Yu et al. (2008a), and refined in Wu et al. (2017); Zhao & Park (2017); Jensen et al. (2020) instead consider spike train models using a Gaussian process prior on \mathbf{x} , which only enforces smoothness, not Markovianity, in the latent dynamics. However, inference using Gaussian processes is computationally quadratic in the number of time points, requiring additional approximations to remain tractable thus these techniques are typically used for very short neural datasets unlike the $\mathcal{O}(\text{hours})$ -long datasets we consider here.

To model complex non-linear, but Markovian, transition structures and alleviate some time scaling issues of GP methods, LFADS (Pandarinath et al., 2018) uses a Recurrent Neural Network to model latent dynamics. While LFADS is capable of modelling a wide range of firing patterns and temporal dynamics, its linear-exponential intensity function model will, again, not capture the complex tuning properties of grid cells and place cells. Moreover, LFADS comes with expensive training overheads and hyperparameters which are reportedly hard to tune (Keshtkaran et al., 2022). Pi-VAE (Zhou & Wei, 2020) uses a Variational Autoencoder (Kingma & Welling, 2014) to learn both a generative model and a latent decoding network for latent-modulated spike events. Finally, CEBRA (Schneider et al., 2023) is a neural network based technique that learns a deterministic encoder mapping spikes to latents using Noise–Contrastive Estimation. CEBRA focuses on decoding and does not natively learn intensity functions, which are of primary interest in our setting. Of these methods only pi-VAE and CEBRA exploit behaviour to find latent variables (pi-VAE uses behaviour labels to define a prior over latent variables, CEBRA uses behaviour as labels for a contrastive loss function). To our knowledge, SIMPL is the first technique to explore using behaviour as an initialisation.

4 Results

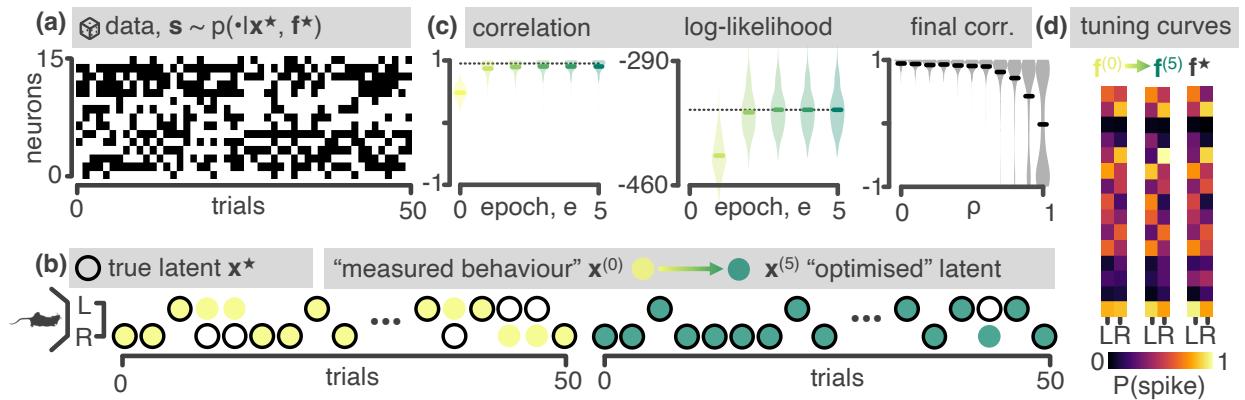

Figure 2: A two-alternative forced choice task (2AFC) toy-model. (a) Data generation: Spikes are sampled from a simple generative model. For each of $T=50$ independent trials a random binary latent — analogous to a “left” or “right” choice — is encoded by a population of $N=15$ neurons with randomly initialized tuning curves. (b) Model performance: Starting from a noisy estimate (yellow) of the true latent (black) where a fraction $\rho = 0.5$ of trials are resampled, SIMPL-R recovers the true latent variables (green) with high accuracy. (c) Left: Correlation between $\mathbf{x}^{(e)}$ and \mathbf{x}^* . Middle: Log-likelihood, $\log p(\mathbf{s}|\mathbf{x}^{(e)}, \mathbf{f}^{(e)})$. Right: Final correlation between $\mathbf{x}^{(5)}$ and \mathbf{x}^* as a function of initialization noise ρ . Violin plots show distributions over 1000 randomly seeded datasets, dotted lines show ceiling performance of a perfectly initialized model ($\mathbf{x}^{(0)} = \mathbf{x}^*$) (d) Tuning curves.

4.1 Toy model of a discrete latent variable task

Before testing SIMPL on a large temporally continuous dataset we constructed a smaller dataset akin to a discrete two-alternative forced choice task (2AFC) (Fig. 2) — a widely studied decision-making paradigm (Platt & Glimcher, 1999; Bogacz et al., 2006; Znamenskiy & Zador, 2013; Lieder et al., 2019). The true latent states $\mathbf{x}_t^* \in \{0, 1\}$ are binary and have no temporal structure (here subscript t indexes *trials* not time), analogous to a series of random “left” or “right” choices (Fig. 2b). This latent state is stochastically encoded by a population of neurons with random tuning curves giving the Bernoulli emission probabilities under each latent state:

$$f_i^*(\mathbf{x}) = \begin{cases} f_{i0} \sim \mathcal{U}(0, 1) & \mathbf{x} = 0, \\ f_{i1} \sim \mathcal{U}(0, 1) & \mathbf{x} = 1, \end{cases}$$

$$\mathbf{x}_t^* \sim \text{Bernoulli}(0.5) \quad \text{and} \quad s_{it} | \mathbf{x}_t \sim \text{Bernoulli}(f_i^*(\mathbf{x}_t^*)).$$

Data is then sampled for $T = 50$ trials and $N = 15$ neurons as shown in Fig. 2. Initial conditions, $\mathbf{x}_t^{(0)}$, are generated from the true latent by randomly resampling a fraction of trials $\rho = 0.5$ (Fig. 2b). This partial resample represents an initial discrepancy between the behavioural measurement and the true internal state of the agent.

We perform inference on this dataset using a reduced version of the model (SIMPL-R). In the M-step, tuning curves were fitted by calculating the average activity of a neuron across each latent condition (e.g. $f_i^{(e)}(\mathbf{x}) = \sum_t s_{ti} \delta(\mathbf{x}_t^{(e)}, \mathbf{x}) / \sum_t \delta(\mathbf{x}_t^{(e)}, \mathbf{x})$, conceptually similar to KDE). For the E-step, each latent was the decoded according to the maximum likelihood estimate under the observed spikes and tuning curve estimates from the previous epoch: $\mathbf{x}_t^{(e+1)} = \arg \max_{\mathbf{x}} \sum_i \log p(s_{ti} | \mathbf{x}, f_i^{(e)})$ (there is no time dependence between latents, thus no Kalman smoothing). This process was repeated for 5 epochs and, with high reliability, converged on the true latents after approximately two (Fig. 2c & d, distributions show repeat for 1000 randomly seeded datasets, dotted lines show ceiling performance on a model perfectly initialized with noiseless $\mathbf{x}^{(0)} = \mathbf{x}^*$). We repeated this experiment for various values of ρ : latent recovery was almost perfect when ρ was small (i.e. when the initial conditions were close to the true latent), dropping off as ρ approached 1. At $\rho = 1$ when the conditions were *completely* random, the model was biased to recover a latent space that is either perfectly correlated or perfectly anti-correlated (“left” \leftrightarrow “right”) with the true latent (Fig. 2c, right), a valid isomorphism discussed more in the upcoming sections.

4.2 Continuous synthetic data: 2D grid cells

Next we tested SIMPL on a realistic navigational task by generating a large artificial dataset of spikes from a population of $N = 225$ 2D grid cells — a type of neuron commonly found in the medial entorhinal cortex which activate on the vertices of a regular hexagonal grid (Hafting et al., 2005) — in a 1 m square environment. Grid cell tuning curves, \mathbf{f}^* , were modelled as the thresholded sum of three planar waves at 0° , 60° and 120° to some offset direction (a commonly used model within the computational neuroscience literature (George et al., 2024a)) and, as observed in the brain, cells were arranged into three discrete modules, 75 cells per modules, of increasing grid scale from 0.3–0.8 m (Fig. 3c). Each cell had a maximum firing rate of 10 Hz. A latent trajectory, \mathbf{x}^* , was then generated by simulating an agent moving around the environment for 1 hour under a smooth continuous random motion model replicating rodent foraging behaviour. Data was sampled at a rate of 10 Hz giving a total of $T = 36,000$ time bins ($\sim 800,000$ spikes). All data was generated using the RatInABox package (George et al., 2024a).

$$\mathbf{x}^* \sim \text{Smooth-continuous-random-walk} \quad \text{and} \quad s_{it} | \mathbf{x}_t^* \sim \text{Poi}(\mathbf{f}_i^{\text{GC}}(\mathbf{x}_t^*)) \quad (3)$$

The initial latent trajectory, $\mathbf{x}^{(0)}$, was generated by adding smooth Gaussian noise to the latent \mathbf{x} such that, on average, the true latent and initial condition differed by 20 cm (Fig. 3a, top panel). This discrepancy, modelling the agent’s own uncertainty in their position and/or a measurement error, was sufficient to obscure almost all structure from the initial grid cell tuning curves $\mathbf{f}^{(0)}(\mathbf{x})$ (Fig. 3b, top).

To assess performance we partition the spike data matrix, \mathbf{s} , into testing and training sets, $\mathcal{S}_{\text{test}}, \mathcal{S}_{\text{train}}$. Inference is performed solely on the training set and we then track the log-likelihood of data in both sets (Fig. 3d, left), e.g. $\ell^{(e)} = |\mathcal{S}_{\text{test}}|^{-1} \sum_{(i,t) \sim \mathcal{S}_{\text{test}}} \log p(s_{ti} | \mathbf{x}_t^{(e)}, \mathbf{f}_i^{(e)})$. This partitioning requires careful consideration: entire time intervals cannot be withheld for testing without impairing the model’s ability to infer the latent over this period. Likewise, entire neurons cannot be withheld without impairing the model’s capacity to estimate their tuning curves. Instead, we adopt a speckled train-test mask previously used in latent variable modelling set-ups (Williams et al., 2020) which withholds for testing extended chunks of time bins arranged in an irregular “speckled” pattern across the data matrix (totalling 10% of the data). We also calculate the Euclidean distance between the true and latent trajectory (Fig. 3d, middle-left), $T^{-1} \sum_t \|\mathbf{x}^{(e)}(t) - \mathbf{x}_t\|_2$, the epoch-to-epoch change in the tuning curves (Fig. 3d, middle-right) and the

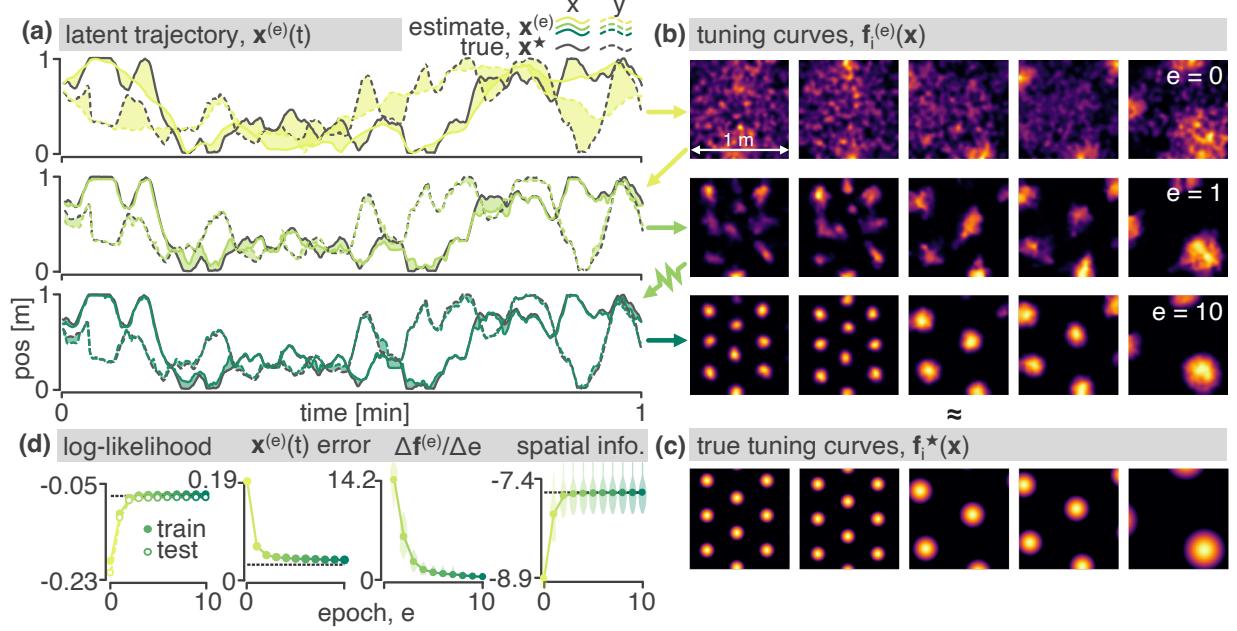

Figure 3: Results on a synthetic 2D grid cell dataset. An artificial agent locomotes a 1 m square environment for 1 hour ($\Delta t = 0.1$ s). Spikes are generated from $N=225$ artificial grid cells. (a) Estimated latent trajectories shown for epochs 0, 1 and 10. x and y positions are denoted by dotted and dashed lines respectively. Initial conditions are generated from the true latent (black) by the addition of smooth continuous Gaussian noise. (b) Tuning curve estimates for 5 exemplar grid cells at epochs 0, 1 and 10. (c) Ground truth tuning curves. (d) Performance metrics: *Left:* log-likelihood of the train and test spikes (averaged per time step, dotted line shows ceiling performance on a model initialized with the true latent). *Middle-left:* Euclidean distance between the true and estimated latent trajectories (averaged per time step). *Middle-right:* Epoch-to-epoch change in the tuning curves. *Right:* Cell spatial information. Violin plots, where shown, display distributions across all 225 neurons.

entropy (hereon called “spatial info”, Fig. 3d, right) of the normalized tuning curves as a measure of how spatially informative they are.

SIMPL was then run for 10 epochs (total compute time 39.8 CPU-secs on a consumer grade laptop). The true latent trajectory and receptive fields were recovered almost perfectly and the log-likelihood of both train and test spikes rapidly approached the ceiling performance with negligible overfitting.

Influence of behavioural initializations on performance Latent variable models trained with EM can experience two issues that usually complicate the scientific interpretability of their results. The first concerns the *quality* of the solution; does the algorithm converge on a good model of the data which predicts the spikes well? The second issue concerns *identifiability*; even if the recovered latent trajectory and tuning curves ($\mathbf{f}^{(e)}, \mathbf{x}^{(e)}$) are of high quality, they may differ from the true ones ($\mathbf{f}^*, \mathbf{x}^*$) by some invertible “warp” ϕ in a way that does not affect the overall goodness of fit of the model. While SIMPL is a latent variable model, we show that behavioural initialization drastically minimizes the severity of both of these issues.

To do so, we first assess the absolute goodness-of-fit of SIMPL by computing the correlation between the estimated instantaneous firing rates $f_t^{(e)}(\mathbf{x}_t^{(e)})$ (a quantity invariant to warping) and the true ones. Our analysis shows that SIMPL converges to a highly accurate model ($r=0.98$) under behavioural initialization, but to a less accurate (though still quite accurate) one ($r = 0.87$) when initialized with a random latent trajectory which is uncorrelated with behavior. Second, we estimate, quantify and visualize the warp map ϕ between SIMPL’s estimates ($\mathbf{f}^{(e)}, \mathbf{x}^{(e)}$) and the ground truth ($\mathbf{f}^*, \mathbf{x}^*$). We obtain this estimate by finding a mapping from the discovered latent space to the true latent space which minimizes the L2 difference between the tuning curves ($\phi(\mathbf{x}) = \arg \min_y \| \mathbf{f}^*(y) - \mathbf{f}^{(e)}(\mathbf{x}) \|_2$). We then quantify the “warpness” of this mapping by calculating the average distance between \mathbf{x} and $\phi(\mathbf{x})$ across the environment, normalized by its characteristic length scale (1 m). This warp distance should be 0 for total un-warped models and $\mathcal{O}(1)$ for heavy warps. We find that in addition to perfectly fitting the data, the solution found by SIMPL under behavioural initialization is minimally warped (warp dist = 0.050). In contrast, the good (but imperfect) solution found by SIMPL under random initialization is heavily warped (warp dist. = 0.498) in a fragmented manner. These results are shown in Fig. 4 and

strongly motivate the use of behavioural initializations in latent variable models as an effective mean to encourage convergence towards latent spaces which are both accurate and un-warped with respect to the ground truth.

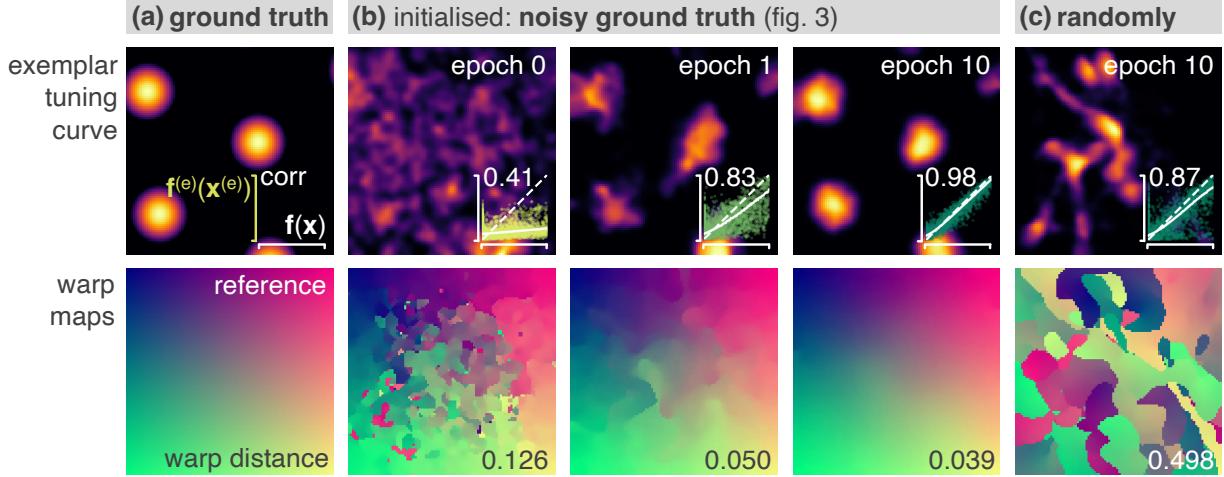

Figure 4: Latent manifold analysis: **(Top)** Exemplar tuning curve in the ground truth latent space **(a)**, the latent space discovered by behaviourally-initialised-SIMPL after 0, 1 and 10 epochs **(b)** and the latent space discovered by SIMPL initialized with a random latent trajectory **(c)**. Inset scatter plots show the true and predicted firing rates of all neurons across all times as well as their correlation values (“accurate” models have higher correlations). **(Bottom)** Visualizations of the warp functions mapping each latent space to the “closest” location in ground truth as measured by the distance between the tuning curves population vectors.

Comparison to CEBRA We compared SIMPL to a popular latent variable extraction technique called CEBRA (Schneider et al., 2023). Unlike SIMPL which uses behaviour as an initialisation, CEBRA learns latent embeddings directly from spikes by training a deep neural network to minimise a contrastive loss function with behaviour as the labels. We trained CEBRA on our synthetic grid cell dataset using out-of-the-box hyperparameters² training for the default 10000 iterations. After training we aligned the latent to behaviour and observed that CEBRA, like SIMPL, found a latent trajectory (Fig. 5a, blue) very close to the true latent (Fig. 5a, black). CEBRA’s latent embedding was noisier than SIMPL’s (a likely consequence of the explicit smoothing we perform) and had significantly larger final error (9.2 cm vs 4.0 cm). Since CEBRA doesn’t explicitly learn a generative model in order to visualise tuning curves we applied our standard KDE fitting procedure (an “M-step”) to the CEBRA latents. The resulting grid cells but remained blurry relative to the ground truth (but were better than behaviour), in comparison to SIMPL, which produced sharp, well-defined grid fields (Fig. 5b) close to the ground truth. CEBRA took just over 23 minutes to train on a consumer laptop with 8-CUs compared to just under 40 seconds for SIMPL on the same machine.

4.3 Hippocampal place cell data

Finally, we test SIMPL on a neural dataset from $N = 226$ hippocampal neurons recorded from a rat as it foraged in a large 3.5 m by 2.5 m environment for 2 hours (full details can be found in Tanni et al. 2022). The data was binned at 5 Hz ($dt = 0.2s$ giving $T = 36,000$ data samples, total $\sim 700,000$ spikes). Place cells are a type of neuron commonly found in the hippocampus which activate when an animal is in a specific location in space (its “place field”) and, like grid cells, are thought to be a key component of the brain’s navigational system (O’Keefe, 1978). In large environments place cells are known to exhibit tuning curves with multiple place fields (Park et al., 2011).

We initialized SIMPL using the measured position of the animal and optimized for 10 epochs. The log-likelihood of test and train spikes increased, Fig. 6b, converging after approximately 4 epochs (compute time 41.2 CPU-secs). Place

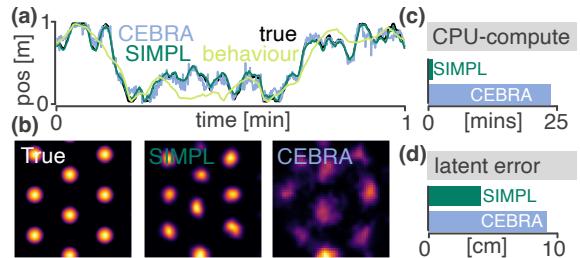

Figure 5: Comparison between SIMPL and CEBRA.

²with the exception that we turned ‘off’ normalisation so outputs weren’t normalised onto a sphere

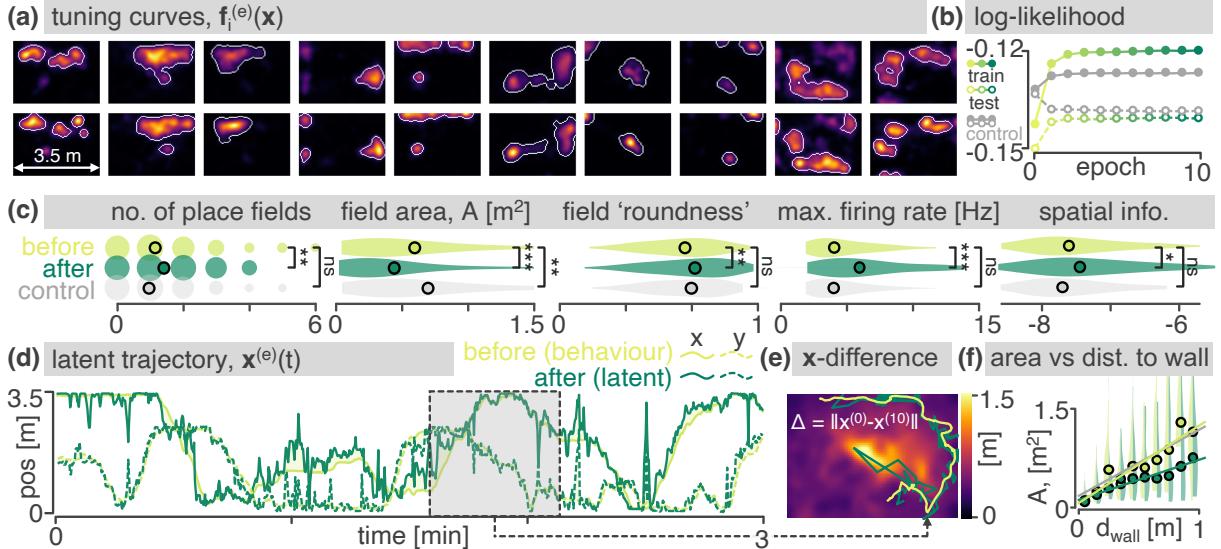

Figure 6: Results on a hippocampal place cell dataset collected by Tanni et al. (2022). **(a)** Exemplar tuning curves before and after optimization. Automatically identified place field boundaries shown in white. **(b)** Log-likelihood of test and train spikes. Equivalent results for a control model — fitted with spikes resampled from the behavioural place fields, $s_{\text{control}} \sim p(\cdot | \mathbf{x}^{(0)}, \mathbf{f}^{(0)})$ — shown in grey. **(c)** Place field (before, after, control-after) analysis. Violin plots show the distributions over all place fields / place cells. **(d)** The final latent trajectory estimated from SIMPL (green) overlaid on top of the behaviour (used as initial conditions) (yellow). x and y coordinates shown with dotted and dashed lines respectively. **(e)** Behavioural discrepancy map: the average discrepancy $\|\mathbf{x}_t^{(0)} - \mathbf{x}_t^{(10)}\|_2$ as a function of the optimized latent $\mathbf{x}^{(10)}$. Overlaid is a snippet of the behavioural vs optimized true latent trajectory. **(f)** Median place field sizes, and distributions, as a function of the distance to the nearest.

fields were automatically identified by thresholding the activity of each neuron at 1 Hz and identifying contiguous regions of activity with a peak firing rate above 2 Hz and a total area less than half that of the full environment, similar to previous work (Tanni et al., 2022).

Tuning curves were visibly sharper after optimization, Fig. 6a; diffuse place fields shrunk (e.g. see the third exemplar tuning curve) or split into multiple, smaller fields (second exemplar) (Fig. 6a). Occasionally, new place fields appeared (fourth exemplar) or multiple place fields merged into a single larger field (fifth exemplar). Statistically, tuning curves had significantly more individual place fields (+19%, mean $1.14 \rightarrow 1.41$ per cell, $p = 0.0035$ Mann Whitney U tests), substantially higher maximum firing rates (+45%, median $4.2 \rightarrow 6.1$ Hz, $p = 9.8 \times 10^{-7}$) and were more spatially informative ($p = 0.038$). Individual place fields were substantially smaller (-25%, median $0.59 \rightarrow 0.44$ m 2) and rounder (+8%, median $0.63 \rightarrow 0.68$, $p = 0.0037$). Notably only *place* cells — defined as cells with at least one place field — showed significant changes in their tuning curves whilst non-place cells were statistically unaffected (data not shown).

To ensure that these changes were not an artefact of the SIMPL algorithm we generated a control dataset by resampling spikes from the behaviour-fitted tuning curves, $s_{\text{control}} \sim p(\cdot | \mathbf{x}^{(0)}, \mathbf{f}^{(0)})$. Control spikes thus had very similar temporal statistics and identical tuning curves to those in the original dataset but, crucially, were generated from a known ground truth model exactly equal to the initialization. Thus, any changes to the control spike tuning curves under SIMPL optimization can be considered artefactual and not fundamental to the underlying neural data. Notably, no significant effect of optimization on the control data (except for a slight *increase* in field area) was observed and all measured effects — though statistically *insignificant* — pointed in the *opposite* direction to those observed in the real data (except for roundness) (Fig. 6c). This control provides strong evidence that the changes observed in the real data are genuine and reflect the true nature of neural tuning curves in the brain.

After 10 iterations of optimization the latent trajectory $\mathbf{x}^{(10)}$ remained highly correlated with the behaviour ($R^2 = 0.86$, fig. 6d) occasionally diverging for short period as the latent “jumped” to and from a new location, as if the animal was mentally teleporting itself (one such “jump” is visualized in Fig. 6e). The close correspondence between the optimized latent and the behaviour allows us to directly compare when, and where, they diverge. We calculated the discrepancy between the optimized latent and the behaviour at each time point, $\|\mathbf{x}_t^{(0)} - \mathbf{x}_t^{(10)}\|_2$, and visualized this as a heat map overlaid onto the latent space (Fig. 6e). Discrepancy was minimal around the edges of the environment and peaked near the centre, consistent with the hypothesis that sensory input is less reliable in the centre of the environment (where

there are fewer visual and tactile cues) to guide self-localisation resulting in a larger average discrepancy between the optimized latent and the behaviour.

Tanni et al. (2022) found that place field size increased with distance from the nearest wall in the environment. Our observation — that latent-behaviour discrepancy is highest in the centre of the environment — suggests a possible explanation: place fields in the centre of the environment are not larger but *appear* larger because they are distorted and blurred by the discrepancy which is largest near the centre of the environment. To test this we binned place fields according to their distance to the nearest wall (measured with respect to the place fields centre of mass) and plotted the median field size against distance (Fig. 6f). Optimized place fields, much like behavioural place fields, were the smallest near the walls and grew with distance (replicating (Tanni et al., 2022)), but this correspondence broke down around ~ 0.5 m after which the optimized size distribution flattened off (something not observed in the control). A majority of the shrink in place field size thus came from larger place fields near the centre of the environment not the smaller ones near the walls. This result suggests that a substantial fraction of the increased size of place fields away from walls is not a fundamental feature of the neural tuning curves themselves but can be attributed to a behaviour-induced distortion in the tuning curves, an artefact which can be corrected for by optimising the latent with SIMPL.

5 Discussion

We introduced SIMPL, a tool for optimizing tuning curves and latent trajectories using a technique which refines estimates obtained from behaviour. It hinges on two well-established sub-routines — fitting and decoding — which are widely used by both experimentalists and theorists for analysing neural data. By presenting SIMPL as an iterative application of these techniques, we aim to make latent variable modelling more accessible to the neuroscience community.

Furthermore, we see SIMPL as a specific instance of a broader class of latent optimization algorithms. In principle *any* arbitrary curve fitting procedure and *any* arbitrary decoder could be coupled into a candidate algorithm for optimizing latents from neural data. Our specific design choices, while attractive due to their conceptual simplicity, will also come with limitations. For example, we predict KDE won't scale well to very high dimensional latent spaces (Györfi et al., 2006). In these instances users could consider substituting this component with a parametric model, e.g. a neural network, which are known to perform better in high dimensions (Bach, 2017), potentially at the cost of compute time.

Our synthetic analysis focussed on settings where behaviour and the true latent differed only in an unbiased manner. It would be interesting to determine if SIMPL's strong performance extends to more complex perturbations. In the brain, fast, non-local and asymmetric perturbations are common; for instance “replay” Carr et al. (2011) where the latent jumps to another location in the environment. Likewise, during theta sweeps (Maurer et al., 2006), the encoded latent moves away from the agent. This forward-biased discrepancy could theoretically induce a backward-biased skew in behavioral place fields, even if the true tuning curves remain unskewed. If this is the case, latent dynamics — and tools like SIMPL for extracting them — could help reinterpret the predictive nature of place field tuning curves Stachenfeld et al. (2017); Fang et al. (2023); Bono et al. (2023); George et al. (2023), similar to how latent optimization reduced the asymmetry in place field sizes further from walls (Fig. 6f).

Supplementary Material for “SIMPL: Scalable and hassle-free optimization of neural representations from behaviour”

A Background

A.1 Expectation Maximization

Expectation Maximization (EM, Dempster et al. 1977) is a widely used paradigm to perform statistical estimation in latent variable models. The goal of EM is to maximize the *Free Energy*, a lower bound on the log-likelihood $\log p(\mathbf{s}; \mathbf{f})$ of the data, given by (following the notations of Section 2.1):

$$\mathcal{F}(\mathbf{f}, q) := \mathbb{E}_{q(\mathbf{x})}[\log p(\mathbf{x}, \mathbf{s}; \mathbf{f})] - \mathbb{E}_{q(\mathbf{x})}[\log q(\mathbf{x})] \leq \log p(\mathbf{s}; \mathbf{f}),$$

where q is some probability distribution on the latent variable \mathbf{x} . Importantly, for a given set of intensity functions \mathbf{f} , \mathcal{F} is maximized, and the lower bound becomes “tight”, at $q^* := p(\mathbf{x}|\mathbf{s}; \mathbf{f})$, i.e. the posterior distribution of the latent variable given the \mathbf{s} and \mathbf{f} . Moreover, for a fixed q , the only \mathbf{f} -dependent term in \mathcal{F} is $\mathbb{E}_{q(\mathbf{x})}[\log p(\mathbf{x}, \mathbf{s}; \mathbf{f})]$. To maximize $\mathcal{F}(\mathbf{f}, q)$ — and thus also increase the log-likelihood — EM produces a sequence $(\mathbf{f}^{[e]})_{e \geq 0}$ of parameters $\mathbf{f}^{[e]}$ by invoking, at each step e and given $\mathbf{f}^{[e-1]}$, two well known subroutines:

- **E-step:** Define $q^{[e]} := p(\mathbf{x}|\mathbf{s}; \mathbf{f}^{[e-1]})$; compute $\mathcal{F} \mapsto \mathbb{E}_{q^{[e]}}[\log p(\mathbf{x}, \mathbf{s}; \mathbf{f})]$
- **M-step:** Compute $\mathbf{f}^{[e]} := \arg \max_{\mathbf{f}} \mathcal{F}(\mathbf{f}, q^{[e]}) = \arg \max_{\mathbf{f}} \mathbb{E}_{q^{[e]}}[\log p(\mathbf{x}, \mathbf{s}; \mathbf{f})]$

with the property that $\log p(\mathbf{s}; \mathbf{f}^{[e]}) \geq \log p(\mathbf{s}; \mathbf{f}^{[e-1]})$ for all e , grounding the use of EM to maximize the likelihood of the data. As the E-step computes specific posterior expectations, a tractable E-step often implies the ability to compute in particular posterior means and variances, the most valuable expectations in the context of decoding the latent variable from behaviour. Thus, in the context of neural data, EM offers a framework to both estimate intensity functions via maximum likelihood, and to ‘decode’ the variable encoded by the neurons, here by taking the mean of the posterior.

Finally, note that while the E-step writes an expectation under the full posterior $q^{[e]} := p(\mathbf{x}|\mathbf{s}, \mathbf{f}^{[e-1]})$, only specific marginals of this posterior may actually be needed depending on the structure of the joint distribution, as further discussed in Section A.2.

Impossibility of Exact EM for Gaussian-Modulated Poisson Processes The *E*-step of the EM algorithm requires computing a function *defined* as an expectation w.r.t $p(\mathbf{x}|\mathbf{s}; \mathbf{f}^{[e-1]})$. In the case of Hidden Markov Models, such expectations are intractable to compute in closed form, unless the latent variable \mathbf{x} is discrete, or both the transition and the emission probabilities are Gaussian (with mean and variance depending linearly on \mathbf{x} , Rauch et al. 1965). In particular, exact inference in the model described in Section 2.1 is impossible because the emission probabilities are Poisson with mean given by a non-linear function of \mathbf{x} via each neurons tuning curve.

In order to perform statistical inference for our spike train model, SIMPL runs an approximation of Exact EM, which we detail below. At a high level the goal is to convert the non-linear, non-Gaussian spiking observations, into a variable which is linear and Gaussian with respect to the latent, thus can be solved using a Kalman smoother.

A.2 Linear Gaussian State Space Models and Kalman Smoothing

Linear Gaussian State Space Models (LGSSM) are dynamical systems of the form:

$$\begin{aligned} \mathbf{z}_{t+1} &= F_t \mathbf{z}_t + \epsilon_t, & \epsilon_t &\sim \mathcal{N}(0_d, Q_t) \\ \mathbf{x}_t &= H_t \mathbf{z}_t + \delta_t, & \delta_t &\sim \mathcal{N}(0_m, R_t). \end{aligned} \tag{4}$$

where $\mathbf{z} \in \mathbb{R}^d$, $\mathbf{x} \in \mathbb{R}^m$, $F_t, Q_t \in \mathbb{R}^{d \times d}$, $H_t \in \mathbb{R}^{p \times d}$ and $R_t \in \mathbb{R}^{m \times m}$. LGSSMs can be used as latent variable models given some observed data \mathbf{x} , where \mathbf{z} is treated as a latent variable. While these models are limited in their expressiveness, their benefits are that inference (and in setting, “E-steps”) can be done very efficiently: not only is the posterior $p(\mathbf{z}_1, \dots, \mathbf{z}_T | \mathbf{x}_1, \dots, \mathbf{x}_T)$ a Gaussian distribution (of dimension Td), but all of its marginals and pairwise marginals $p(\mathbf{z}_t | \mathbf{x}_1, \dots, \mathbf{x}_T), p(\mathbf{z}_t, \mathbf{z}_{t+1} | \mathbf{x}_1, \dots, \mathbf{x}_T)$ (crucially, the only distributions needed for learning the parameters of LGSSM via EM) can be computed jointly in $\mathcal{O}(T)$ time using a technique known as Kalman Smoothing (Kalman, 1960; Rauch et al., 1965). Such a scaling contrasts with naive binning-based alternatives for (approximate) inference in continuous, non-Gaussian State Space Models, which require maintaining an estimate of each bin — a vector of size n

(no. bins) where n grows *exponentially* with the dimension of the latent space, as used in e.g. Denovellis et al. 2021. Instead, for LGSSMs, the Gaussianity means only the mean and covariance of the marginal posterior distributions — of size d and d^2 respectively — need to be stored. This is not memory intensive and, perhaps more importantly, the Kalman Filter proceeds to compute them in a combined $\mathcal{O}(T)$ time. In our experiments, we found the cost of the Kalman Filter to be negligible relative to the KDE evaluations which are the main computational bottleneck of SIMPL.

B SIMPL as an approximate EM algorithm

B.1 MLE-backed Approximate E-Step

Instead of $q^{[e]} = p(\mathbf{x}|\mathbf{s}; \mathbf{f}^{[e-1]})$, SIMPL computes an approximation $\hat{q}^{[e]}$ to $q^{[e]}$, allowing for both statistical estimation and uncertainty-aware trajectory decoding. As a first step towards obtaining $\hat{q}^{[e]}$, SIMPL first performs Maximum Likelihood Estimation (MLE) on the latent trajectory \mathbf{x} . Instead of returning a posterior on \mathbf{x} , MLE returns a point estimate of the *true* trajectory that led to the observed spike train \mathbf{s} . In particular, MLE does not use the prior knowledge encoded by $p(\mathbf{x})$. The MLE $\hat{\mathbf{x}}$ of \mathbf{x} given \mathbf{s} is given by:

$$\begin{aligned}\hat{\mathbf{x}} &= \arg \max_{\mathbf{x}} \log p(\mathbf{s}|\mathbf{x}; \mathbf{f}^{[e-1]}) = \arg \max_{\mathbf{x}} \sum_{t=1}^T \sum_{i=1}^N \log p(\mathbf{s}_{it}|\mathbf{x}_t; \mathbf{f}^{[e-1]}) \\ \implies \hat{\mathbf{x}}_t &= \arg \max_{\mathbf{x}_t} \sum_{i=1}^N \log p(\mathbf{s}_{it}|\mathbf{x}_t; \mathbf{f}^{[e-1]}).\end{aligned}$$

The second equality follows from the conditional independence structure of the HMM. This maximization problem can be solved independently for each t , yielding the formula for $\hat{\mathbf{x}}_t$ given by the third equality. As a function of \mathbf{s} , the MLE $\hat{\mathbf{x}}$ is itself a random variable. In the many neurons limit, under certain regularity assumptions, the distribution of this random variable converges to a Gaussian, a fact known as *asymptotic normality*. We restate a formal statement of this result in the case of independent, but non identically distributed observations³ originally established in Bradley & Gart (1962), and reformulated using the notations of the model at hand. For simplicity, we will consider the case where only P distinct intensity functions $\mathbf{f}_1, \dots, \mathbf{f}_P$ exist, although versions of this result exist without this assumption.

Theorem B.1 (Asymptotic Normality of the MLE). *Let $\mathbf{x}_t^* \in \mathbb{R}^d$. Let $\mathbf{s} = (s_{1t}, \dots, s_{Nt})$ be independent random variables with probability densities $p(s_{it}|\mathbf{x}_t^*; \mathbf{f}_{t(i)})$, where $t(i) \in 1, \dots, P$ is the index of the intensity function $f_{t(i)}$ that generated the spike train s_{it} . For $p \in 1, \dots, P$, denote n_p the number of times the intensity function f_p appeared in the sequence $\mathbf{f}_{t(i)}$. Assume that the MLE $\hat{\mathbf{x}}_t$ exists and it is unique. Then, under mild regularity conditions, we have:*

$$\sqrt{N} (\hat{\mathbf{x}}_t - \mathbf{x}_t^*) \xrightarrow[N \rightarrow \infty]{\text{d}} \mathcal{N}(0, \mathcal{I}(\mathbf{x}_t^*)^{-1})$$

where $\mathcal{I}(\mathbf{x}_t^*) := \sum_{p=1}^P \mu_p \mathbb{E}_{p(s_{it}; \mathbf{f}_p)} \text{Hess}(\log p(s_{it}|\mathbf{x}_t^*; \mathbf{f}_p))$ is the Fisher Information matrix of the model at \mathbf{x}_t^* , $\xrightarrow{\text{d}}$ means convergence in distribution, and we defined $\mu_p := \lim_{N \rightarrow \infty} \frac{n_p}{N}$.

The asymptotic Gaussianity of the MLE in the many neurons limit suggests performing approximate inference in a surrogate Hidden Markov Model, with the same transition probabilities $p(\mathbf{x}_{t+1}|\mathbf{x}_t)$ as the original ones, but where the observations \mathbf{s} are replaced by the previously computed MLE $\hat{\mathbf{x}}$ of the latent variable. Leveraging Theorem B.1, SIMPL approximates the emission probabilities $p(\hat{\mathbf{x}}_t|\mathbf{x}_t)$ by the Gaussian distribution $\mathcal{N}(\mathbf{x}_t, \Sigma_t)$, where $\Sigma_t := (N\mathcal{I}(\hat{\mathbf{x}}_t))^{-1} \approx (N\mathcal{I}(\mathbf{x}_t))^{-1}$. By treating the covariance matrices Σ_t as deterministic instead of depending on \mathbf{x}_t , the variables $(\mathbf{x}_t, \hat{\mathbf{x}}_t)$ form a Linear Gaussian State Space Model, with hidden variables \mathbf{x}_t and observed variables $\hat{\mathbf{x}}_t$ given by:

$$\begin{aligned}\hat{\mathbf{x}}_t | \mathbf{x}_t &\sim \mathcal{N}(\mathbf{x}_t, \Sigma_t) \\ \mathbf{x}_{t+1} | \mathbf{x}_t &\sim \mathcal{N}(\mathbf{x}_t, \sigma_v^2 \mathbf{I}),\end{aligned}\tag{5}$$

for $\sigma_v = v \cdot dt$. This model is precisely an instance of Linear Gaussian State Space Models defined in Equation 4, with latent variable $z_t := \mathbf{x}_t$, observation $\hat{\mathbf{x}}_t$, and the four matrices set to:

$$\begin{aligned}F_t &= \mathbf{I} && \text{(constant)} \\ H_t &= \mathbf{I} && \text{(constant)} \\ Q_t &= \sigma_v^2 \mathbf{I} && \text{(constant)} \\ R &= \Sigma_t && \text{(time-varying).}\end{aligned}$$

³The i.i.d case was established in Fisher (1925)

This correspondence allows SIMPL to compute an approximation of the marginal posterior distributions $p(\mathbf{x}_t|\mathbf{s}) \approx p(\mathbf{x}_t|\hat{\mathbf{x}})$ using Kalman Smoothing (Kalman, 1960; Rauch et al., 1965). This posterior is then used as the approximation $\hat{q}^{[e]}$ to $q^{[e]}$ in SIMPL’s E-step. Finally, $\mathcal{F}(f, \hat{q}^{[e]})$ is approximated by sampling from $\hat{q}^{[e]}$, and computing the empirical average of $\log p(\mathbf{x}, \mathbf{s}; \mathbf{f})$. Importantly, obtaining the MLE estimates $\hat{\mathbf{x}}_t$ can be obtained in parallel for all t ; the only sequential procedure remaining being the Kalman Smoothing step.

B.2 Spike Smoothing as an approximate M-Step

In the M-step, one maximizes $\mathbb{E}_{\hat{q}^{[e]}}[\log p(\mathbf{x}, \mathbf{s}; \mathbf{f})]$ w.r.t to the intensity functions (tuning curves) $\mathbf{f} = (f_1, \dots, f_N)$. This step is often done by specifying a parametric model for each f_i , and then optimizing the parameters. However parametric models come with disadvantages, for example if the true function cannot be accurately represented by the parametric model, the final procedure will suffer from a bias that does not vanish in the large sample limit. While one could use a neural network (whose bias can be made arbitrarily small by increasing the number of neurons), neural networks can be hard to interpret and expensive to train. Instead, SIMPL uses a non-parametric approach that is both training-free and interpretable. To do so, SIMPL samples from its approximate posterior $\tilde{\mathbf{x}} \sim \hat{q}^{[e]}$, and computes a non-parametric estimate (Hodara et al., 2018) of the intensity functions f_i given by:

$$\hat{f}_i^{[e]}(\mathbf{x}) := \frac{\sum_{t=1}^T \mathbf{s}_{it} k(\mathbf{x}, \tilde{\mathbf{x}}_t)}{\sum_{t=1}^T k(\mathbf{x}, \tilde{\mathbf{x}}_t)}. \quad (6)$$

Here, $k : \mathbb{R}^d \times \mathbb{R}^d \mapsto \mathbb{R}_+$ is some kernel function.

We propose an explanation of the above formula as the generalization of an M-step: for a fixed $\hat{q}^{[e]}$, $\mathbb{E}_{p(\mathbf{s})\hat{q}^{[e]}(\mathbf{x})} \log p(\mathbf{s}, \mathbf{x}; \mathbf{f})$ equals (up to a constant) the negative KL divergence between the “data” distribution ⁴
 $p(\mathbf{s})\hat{q}^{[e]}(\mathbf{x}|\mathbf{s})$ and the model $p(\mathbf{s}, \mathbf{x}; \mathbf{f})$. Thus, an M-step can be understood as minimizing this KL divergence approximately, by replacing the expectation over $p(\mathbf{s})$ by an empirical average over the true data \mathbf{s} , an approximation which is asymptotically consistent in the large number of time-steps limit under suitable ergodicity conditions (Billingsley, 1961). SIMPL relaxes this approximation further, replacing the expectation over $\hat{q}^{[e]}(\mathbf{x}|\mathbf{s})$ by a one-sample estimate of it through $\tilde{\mathbf{x}}$. Moreover, it does not use the KL as a loss function, but instead performs model fitting in a non-parametric manner. Under this procedure, the existing guarantees regarding the EM algorithm do not hold – on the other hand, SIMPL’s M-step precisely matches spike smoothing, a fast and standard practice in neuroscience.

C Implementation Details

Below we provide some implementation details that were important to maximize the computational efficiency of the method.

C.1 Maximizing SIMPL’s computational efficiency

C.1.1 Computational bottlenecks in SIMPL

A single evaluation of the log-likelihood $\log p(\mathbf{s}_t|\mathbf{x}_t)$ requires evaluating the KDE-based rate map estimates given in Equation 6, which takes $\mathcal{O}(T)$ time as it involves a sum across timesteps. Moreover, this $\mathcal{O}(T)$ -length calculation will be repeated T -times for each step of the Kalman smoother in order to (1) compute the MLEs $\hat{\mathbf{x}}_t$ (which naively require gradient ascent on $\log p(\mathbf{s}_t|\mathbf{x}_t)$) and (2) evaluate the MLE variance $\Sigma_t := (N\mathcal{I}(\hat{\mathbf{x}}_t))^{-1} = (N\mathbf{H}_x(\log p(\mathbf{s}|\hat{\mathbf{x}}_t))(\hat{\mathbf{x}}_t))^{-1}$. All in all, an exact implementation of SIMPL E-step thus has a quadratic $\mathcal{O}(T^2)$ time complexity, which is prohibitive for long datasets. Moreover, the second-order differentiation needed to compute $\mathcal{I}(\hat{\mathbf{x}}_t)$ is also computationally expensive (formally, it introduces a large constant factor in front of the $\mathcal{O}(T^2)$ term). In the next sections, we describe additional approximations which allow SIMPL to estimate the MLE and its variance in $\mathcal{O}(T)$ time and without differentiating the rate maps.

C.1.2 Linear-time, MLE estimation

Naive gradient-based solution The naive way to calculate the MLE $\hat{\mathbf{x}}_t$ is to evaluate all N tuning curves (recall each evaluation costs $\mathcal{O}(T)$) for some location \mathbf{x} , use these to establish the log-likelihood $\log p(\mathbf{s}_t|\mathbf{x})$, calculate the gradient of this log-likelihood w.r.t. \mathbf{x} , and then take, for example, k gradient descent steps to find the MLE. This process is repeated for each timestep t , leads to a quadratic time complexity of $\mathcal{O}(kNT^2)$.

⁴We denote $q^k(x)$ by $q^k(x|s)$ to highlight the dependence between x and s .

SIMPL’s approach To compute the MLE in linear time SIMPL bypasses the need to recalculate the tuning curves at each time step by, instead, binning them onto a discretised grid of points once at the start of each iteration.

Formally SIMPL computes n evaluations the tuning curves $\tilde{\mathbf{f}} := (\tilde{\mathbf{f}}_1, \dots, \tilde{\mathbf{f}}_n) := (\mathbf{f}(\mathbf{g}_1), \dots, \mathbf{f}(\mathbf{g}_n))$ on a grid of n points $\mathcal{G} = (\mathbf{g}_1, \dots, \mathbf{g}_n)$. This has time complexity $\mathcal{O}(NnT)$. We use a uniform rectangular grid of points (the smallest rectangle containing the full observed behavioural variable) of spacing dx . For example, in a $1\text{ m} \times 1\text{ m}$ environment with $dx = 0.02\text{ m}$, this would yield a grid of 50×50 points ($n = 2500$).

Then, given $\tilde{\mathbf{f}}$, SIMPL then discretizes the log-likelihood functions $\log p(\mathbf{s}_t | \mathbf{x})$ over that same grid:

$$\begin{aligned}\tilde{l}_{it} &:= \log p(\mathbf{s}_t | \mathbf{g}_i) = \sum_{j=1}^N \log p(s_{tj} | \mathbf{g}_i) = \sum_{j=1}^N \log \frac{e^{-\tilde{f}_{ij}} \tilde{f}_{ij}^{s_{tj}}}{s_{tj}!} \\ &= -\sum_{j=1}^N \tilde{f}_{ij} + s_{tj} \log \tilde{f}_{ij} - \log s_{tj}!\end{aligned}\tag{7}$$

where we noted $\tilde{f}_{ij} := (\tilde{\mathbf{f}}_i)_j$. Finally, given such evaluations, SIMPL set its approximation of the MLE to be

$$\hat{\mathbf{x}}_t := \arg \max_{\mathbf{g} \in \mathcal{G}} \log p(\mathbf{s}_t | \mathbf{g}) = \arg \max_i \tilde{l}_{it}$$

This way of calculating the MLE has linear time complexity yielding an improvement for $n < kT$.

C.1.3 Linear-time derivative-free MLE variance estimation

A similar strategy could be employed to also compute $\mathcal{I}(\hat{\mathbf{x}}_t) := -\mathbf{H}_x(\log p(\mathbf{s}_t | \hat{\mathbf{x}}_t))(\hat{\mathbf{x}}_t)$, which appears in Σ_t . Here \mathbf{H}_x is the Hessian operator defined as $\mathbf{H}_x(f)(x) := \nabla_x^2 f(x)$. To do so, one could compute the Hessian of the rate maps and their logarithm on that grid, from which any $\mathbf{H}_x(\log p(\mathbf{s} | \hat{\mathbf{x}}_t))(\hat{\mathbf{x}}_t)$ at the grid-point-based MLE obtained above can be evaluated as $\mathbf{H}_x(\log p(\mathbf{s}_t | \mathbf{g}_i))(\mathbf{g}_i) = -\sum_{j=1}^N \mathbf{H}_x(f_j)(\mathbf{g}_i) + s_{tj} \mathbf{H}_x(\log f_j)(\mathbf{g}_i)$. However, we found that differentiating \mathbf{f} could be slow. To further improve computational efficiency, SIMPL produces an estimation of Σ_t by instead *estimating the variance of the posterior distribution* $p(\mathbf{x}_t | \mathbf{s}_t) \propto p(\mathbf{x}_t)p(\mathbf{s}_t | \mathbf{x}_t) = p(\mathbf{s}_t, \mathbf{x}_t)$. The posterior variance and the MLE variance are expected to closely match, as discussed in our theoretical justification above. Moreover, as this posterior is available analytically up to the normalizing constant $p(\mathbf{s}_t)$, its variance can be approximately computed by binning $p(\mathbf{x}_t | \mathbf{s}_t)$ onto the same grid \mathcal{G} introduced above, yielding the following fast estimator for Σ_t .

$$\Sigma_t \approx \text{Cov } p(\mathbf{x}_t | \mathbf{s}_t) \approx \frac{\sum_i \tilde{p}_{it} (\mathbf{g}_i - \boldsymbol{\mu}_t)(\mathbf{g}_i - \boldsymbol{\mu}_t)^T}{\sum_i \tilde{p}_{it}}, \quad \boldsymbol{\mu}_t := \frac{\sum_i \mathbf{g}_i \tilde{p}_{it}}{\sum_i \tilde{p}_{it}}\tag{8}$$

where $\tilde{p}_{it} := \exp(\tilde{l}_{it}) = p(\mathbf{s}_t | \mathbf{g}_i)$. Intuitively, this is equivalent to fitting a multivariate Gaussian to the binned likelihood map. The covariance matrix of this Gaussian is then used as an approximation of the MLE variance. We provide a theoretical argument justifying the validity of this formula below.

Theoretical Justification Equation 8 is justified by the Bernstein Von Mises theorem, which states that the difference (in total variation) between the posterior distribution and the distribution of the MLE vanishes in the many neurons limit. We restate this theorem using the notations of our paper, assuming a unique rate map, and without stating some of the required regularity assumptions for simplicity. We refer the reader to (Van der Vaart, 2000, Theorem 10.1, p.141–144) for the full version.

Theorem C.1 (Bernstein-von Mises). *Let $\mathbf{x}_t^* \in \mathbb{R}^d$. Let $\mathbf{s}_t = (s_{1t}, \dots, s_{Nt})$ be i.i.d random variables with probability density $p(\mathbf{s}_t | \mathbf{x}_t^*; \mathbf{f})$. Assume that the MLE $\hat{\mathbf{x}}_t$ exists and it is unique. Then, under mild regularity conditions, for any prior p on \mathbf{x}_t , we have:*

$$\|p(\mathbf{x}_t | \mathbf{s}_t) - \mathcal{N}(\hat{\mathbf{x}}_t, (N\mathcal{I}(\mathbf{x}_t^*))^{-1})\|_{\text{TV}} \xrightarrow[N \rightarrow \infty]{p(\mathbf{s}_t)} 0$$

where $\xrightarrow{p(\mathbf{s}_t)}$ denotes convergence in probability, and $\|\cdot\|_{\text{TV}}$ denotes the Total Variation norm on bounded measures.

From this theorem, we thus have that the (random) posterior distribution behaves (in total variation) as a Gaussian whose covariance matrix is precisely the asymptotic variance of the MLE. Note however that convergence in total variation does not a priori imply convergence of variances. Further work could examine under which assumptions such a convergence of variances may hold. In practice, we found that this approximation yielded a satisfying trade-off between performance and accuracy.

C.2 Iterative Linear Realignment of the trajectories

To improve the identifiability properties and the numerical stability of SIMPL, we also transform the decoded latent trajectory at each iteration using a linear mapping which maximally aligns it with behaviour defined as $\mathbf{x}_t^{(e)} \leftarrow \mathbf{M}\mathbf{x}_t^{(e)} + \mathbf{c}$ where $\mathbf{M}, \mathbf{c} = \arg \min \sum_t \|\mathbf{x}_t^{(0)} - (\mathbf{M}\mathbf{x}_t^{(e)} + \mathbf{c})\|$. This approach ensures the scale, orientation and centre of the optimised latent trajectory are tied to behaviour, preventing accumulation of linear shifts/rotations across iterations and allowing us to interpret the latent relative to, and in the same units as, behaviour. We suspect that performing this alignment on all iterates *after* the optimization would yield similar results. Because the transformed latent necessarily has similar scale to the behaviour — which was used to set the size of the discretised environment — we can reuse the same discrete grid for the latent avoiding the need to rediscretize the environment at each iteration.

C.3 Hyperparameters settings

SIMPL has two model hyperparameters:

- v : the diffusion rate for Kalman smoothing, which sets a prior over expected velocity of the latent variable. Units are in ms^{-1} .
- σ : the bandwidth of the kernel used in the M-step to smooth spikes. Units are in m.

Additionally there are some implementation-specific parameters:

- dx : the bin size for the variance estimation of the MLE. Units are in m.
- dt : the time step of the discretization of the latent variable. Units are in s.
- E : the number of iterations of the EM algorithm.

Finally, in all simulations we used a test fraction of 10% and held out ‘speckled’ data segments of length 1 second to evaluate the performance of the model. We provide in Table 1 the value of these hyperparameters for the Artificial Grid Cell Dataset and the Real Hippocampal Dataset.

Table 1: Hyperparameters settings

Hyperparameter	Artificial Grid Cell Dataset (Fig. 4)	Real Hippocampal Dataset (Fig. 6)
velocity prior, v	0.4 ms^{-1}	1.0^{-1}
KDE bandwidth, σ	0.02 m	0.1 m
arena bin size, dx	0.02 m	0.04 m
time discretisation, dt	0.1 s	0.2 s
number of EM iterations, E	10	10
